ABSTRACT

Midway is an advanced stage discovery, exploration project near Tonopah in southern Nevada. It is a classic pediment discovery covered by 10-30m of transported Quaternary alluvial gravel and active sand dunes along the NE range front of the San Antonio Mountains. The deposit is only exposed in drill holes. No mineralized outcrops are exposed through the cover rocks.

Midway is a low sulfidation, quartz-adularia, bonanza gold vein system. Bonanza gold veins (Figure 1) are generally enclosed in lower grade, disseminated gold and gold bearing stockwork veinlets. Gold is hosted by a sequence of Miocene interbedded volcanics and volcaniclastic sediments (Tmv) and by Oligocene metamorphosed basement rocks of the Palmetto Formation (Op).

The Midway gold deposit was discovered by Kennecott Exploration in the mid 1990’s by drill holes in pediment gravel near silicified, but not mineralized range front outcrops. The property was explored by several companies, but dropped due to low metal prices. The ground was re-staked in 1999 and optioned by Midway Gold Corporation. Midway Gold continued exploration on their own and through a joint venture with Newmont Mining Corporation. Midway Gold drilling in 2005 and 2006 expanded the original Discovery Zone and discovered several new veins. An exploration decline for bulk sampling and test stoping is currently being permitted.

RESULTS from the Discovery Zone geologic model were used to create a property-wide geologic exploration model from the recently compiled 3D project database. The property-wide model incorporates modeled geology, drill hole gold and inverted geophysical results from aeromagnetic, TEM, gravity, CSAMT and IP surveys data utilizing Gocad 3D pattern recognition software.

Geologic modeling of the hanging wall (HW) contact surface of Op basement rocks defines a series of NS trending, composite horizons and gabbronorite bounded by interpreted normal faults. Tertiary volcanism transitions and stratigraphic pinch out against horst blocks that form the Tonopah basin on the NE range front.

INTRODUCTION

Midway is a range front pediment gold discovery entirely covered by 5m to 300m of transported Quaternary alluvial gravel and active sand dunes. The deposit lies along the NE range front of the San Antonio Mountains about 35 km NE of Tonopah, Nevada. Midway is a quartz-adularia, low sulfidation bonanza gold vein system hosted by silicified Miocene interbedded volcanic/volcaniclastic sequence (Tmv) and metamorphosed Ordovician Palmetto Formation (Op) basement rocks.

Over the last two years Midway Gold Corporation, owner, has discovered two bonanza vein zones near the original Discovery Zone and is presently permitting an exploration decline for bulk sampling and test stoping. Midway Gold has logged a number of past drill holes within and near the Discovery Zone and used the information to revise the local geologic model with conventional cross sections and maps. Proximal targets were derived and drill tested. In 2006 new bonanza gold veins were discovered based on the projections from the revised model. The new Hamleton vein discovery is the first bonanza gold vein found within Op basement rocks at Midway and it spans up property-wide, untested gold potential at depth.

LOCATIONS

The Midway project is located 35 km NE of Tonopah, Nevada within a regional, NS trend of major gold districts (Figure 2). The deposit is along state highway 375 at the Belmont cutoff intersection (Figure 2).

APPRAISAL

In the past, the Midway database had been only partially compiled into 2D GIS and was combined with conventional paper cross sections and maps at various scales to consider results and derive targets. Midway Gold compiled and integrated all the project data into Gocad (version 2.0.8) 3D pattern recognition software to support 3D exploration modeling and targeting. 3D geologic contact surfaces, correlations, gold mining and interpretation of inverted geophysics were the basis of the modeling. Surpac software was used to design the exploration decline and complete part of the detailed vein orientation assessment. Surface geochemical data is minimal due to the pediment setting. Drill holes were typically analyzed only for Au and Ag. Results from an orientation soil gas survey were incorporated in the targeting.

DEPOSIT GEOLOGY

The low sulfidation, quartz adularia vein and disseminated gold deposit at Midway is within a NW trending zone with 2.3 km of strike length as presently known (Figure 3). The Midway gold zone dips NE away from the range front and is open down dip and on strike. The discovery of the Dauntless vein zone in 2006, which is hosted by Op basement rocks, opens the depth potential of the entire Midway gold zone for similar bonanza gold veins.

Midway gold host rocks are Tmv interbedded rhyolite, rhyolite lithic and tuff and associated volcaniclastic rocks and Op Ordovician basement rocks. Tmv host rocks are exposed only in drill holes beneath the Quaternary gravel. Op is weakly metamorphosed argillite with sparse interbedded basalt and limestone. Op basement comprises much of the exposed bedrock along the range front of the San Antonio Mountains to the SW of the pediment discovery (Davies, et. al, 1971). Kleinhampel and Zions, 1985, Newmont, 2003). Small rhyolite stock and dike swarms cut Op near the range front (Newmont, 2003) and have silicified and decalcified some of the Op interbedded limestone units.

Most Op gold is present in the basal portion of the Tmv sequence and the upper part of the Op basement. Greater than 1 ppm Au in drill intercepts generally fall is within a 100 m thick, zone that follows the structure contour of the hanging wall contact of the Op unit (Figure 3B).

Detailed 3D modeling of the Op contact, first in the Discovery Zone, and then property-wide in drill holes that cut Op, reveals key structural controls on gold. Figure 3A illustrates the structure contour of the Op hanging wall (HW) contact surface. A NW trending series of NS horsts and grabens are defined by the HW contact surface of the Op and interpreted normal faults (Figure 3A). In detail, gold vein swarms are present above Op basement graben bounding faults and within the crests of the basement horsts (Figure 3 A and B and better illustrated in active 3D views).

Geologic results from core holes drilled in the early 2000’s, lead Midway Gold to focus on re logging drill cuttings and early core holes to unravel Miocene host rock stratigraphy. Basin conglomerate and breccias in the sequence locally control high grade gold. Complex lithofacies transitions of Miocene stratigraphic units and stratigraphic pinch outs are present against the horsts (illustrated in Figure 3B) (Tietz, 2006) and indicate the basement horsts and grabens were tectonically active during Miocene volcanism and sedimentation.

Rhyolite dike swarms cut Op basement rocks and trend parallel to graben bounding faults. The dikes are locally mineralized and are present in the footwall of each known gold zone. The basement faults provided intrusive corridors and later, conduits for gold mineralization.

Documentation of basement fault/gold mineralization controls provided the basis for detailed 3D modeling of bonanza gold veins within the Discovery, Cross and Dauntless zones in order to improve design of the exploration decline. 3D modeling and re logging of all vein intercepts reveal the veins are NS on echelon veins within the NW trending Midway gold zone. The NS are echelon character of the veins is generally supported by an independently derived drill hole gold variogram of N55W (Seibel, 2006).

The NS echelon bonanza vein configuration is significant from an exploration view. Past drilling and conventional cross section modeling of results have been carried out on a NW trending drill grid. The NS strike projections of the interpreted bonanza veins are entirely open and untested in the Discovery and other veins zones (Figure 3A). This substantially increases the proximal, bonanza vein exploration potential of the deposit.

The above-derived geologic framework is supported by the integrated, inverted geophysical surveys. Property-wide aeromagnetic, TEM and gravity surveys and local CSAMT and IP surveys over the Discovery Zone provide mutually consistent patterns relative to the modeled bedrock geology. Reissures correlate with bedrock silicification that envelopes known gold, and highlights potentially altered and untested areas. The main part of the Midway gold deposit correlates with within a NS trending mag low within the NW range front structural grain depicted in the magnetics.

EXPLORATION TARGETS

Proximal bonanza vein targets include the N and S strike projections of known veins, particularly in the vicinity of the exploration decline that will outline the Discovery, Dauntless and Cross vein zones (Figure 3A).

Larger scale targets include the down dip projection of the Midway gold zone itself, within about 50m above and below the Op basement rock contact, along graben bounding faults and near the axes of horsts defined by the modeled hanging wall contacts of the Op surface (Figure 4). In 3D the eight outlying vein targets are not tested, even though some shallow holes have been collared in the targets in the past (Figure 4). The outlying targets hold potential for additional Discovery Zone scale deposits.

On a larger scale, interpretation of the inverted TEM data and surface geology within the San Antonio Mountains establishes a conceptual, mineralized gold porphyry target (Figure 5). It appears the NW trending Midway gold zone lies within a large scale conductive annulus surrounding a central conductive high (Figure 5). Rhyolite dikes and a small stock are present in bedrock within the central conductor and Op limonite interbeds are silicified, locally decalcified, prospected and weakly mineralized with Au. A central rhyolite porphyry target is supported by the presence of mineralized rhyolite dike beneath each of the veins zones within the main Midway gold zone.

ACKNOWLEDGEMENTS

Alan Brahum, President, Midway Gold Corporation focuses on geologic ore controls to guide the exploration drills. His support of the data compilation and 3D integration and modeling has been key in the drilled expansions of the covered deposit. Alan Brahuman and Paul Tietz, past Consultant, re logged much of the core and drill holes in the Discovery Zone. Paul built the conventional cross section model in the Discovery Zone that documents facies changes and stratigraphic pinch outs within host rocks and provide key insights into gold mineralization. Jim Wright, Geophysical Consultant compiled and inverted the geophysical data. We gratefully acknowledge their descriptive and interpretive work that is part of the basis of the 3D modeling and projections presented in this summary.

CONCLUSIONS

Descriptive geology, detailed 3D modeling from compiled and well integrated project data, even in advanced exploration projects, can lead to new insight into geologic gold controls and upside exploration potential. Current 3D exploration modeling techniques place new demands for descriptive, accurate and precise geology be recorded and used along with numerical data do characterize mineralization controls.
